Chapter 3 — Entropy and the Second Law

Extended-reach chapter (May 2026), identification tier. Stamped 2026-09-13 (Keeper, K1895): the same five integers appear here as identifications — formulas that match, mechanisms not claimed — presented on a separate shelf from the derived core so that a reader can trust the core without accepting the reach. Not re-verified line by line since May; the presentation scan found no retired reading in this file except where a dated FIRED note says so. Where this chapter and the Spine (./Spine_DIV5_QM_GR_SM/) or the theorem registry disagree, they win.

Level 1 — one sentence

Entropy is the substrate counting how many K-type configurations match a given macroscopic description ($S = k_B \ln W$ — Boltzmann), and the second law $\Delta S_{\text{total}} \geq 0$ is the substrate's mandatory information-discard in Zone 3 commitment-completion across many Koons ticks, with Shannon-entropy on the substrate's Reed-Solomon-coded GF(128) K-types and thermodynamic entropy being literally the same operation read at different scales.

Level 2 — graduate-physicist precision

3.1 Boltzmann entropy: counting microstates

For a system at fixed energy E with $W(E)$ accessible microstates, the Boltzmann entropy is

$$S = k_B \ln W(E)$$

This is the foundational definition (Boltzmann 1872, 1877; engraved on Boltzmann's gravestone). The constant $k_B = 1.381 \times 10^{-23}$ J/K converts the dimensionless count $\ln W$ to thermodynamic units.

Substrate-mechanism reading: $W(E)$ is the number of substrate K-types with Casimir eigenvalue near E . The entropy is the substrate counting how many

internal configurations match the macroscopic energy. Casey's Principle reads S as “counting” — the depth-0 identity.

3.2 Gibbs entropy: probability-weighted

For a system not at fixed energy but described by a probability distribution $\{p_\lambda\}$ over microstates λ :

$$S = -k_B \sum_{\lambda} p_{\lambda} \ln p_{\lambda}$$

This is the Gibbs entropy (Gibbs 1902), reducing to Boltzmann's $S = k_B \ln W$ for a uniform distribution over W microstates ($p_{\lambda} = 1/W$ for W accessible, $p_{\lambda} = 0$ otherwise).

For the substrate at temperature T , the K-type populations follow Boltzmann distribution $p_{\lambda} = e^{-E_{\lambda}/k_B T} / Z(\beta)$ (Chapter 5); the Gibbs entropy becomes

$$S(\beta) = k_B [\ln Z(\beta) + \beta \langle E \rangle]$$

a closed-form expression in terms of the partition function Z .

3.3 Shannon entropy: information theory unification

Shannon 1948 defined the entropy of a probability distribution $\{p_n\}$ as

$$H(X) = - \sum_n p_n \log_2 p_n$$

(bits, with $\log_2$). This is *operationally identical* to Gibbs entropy up to the choice of units: $S_{\text{Gibbs}} = k_B \ln 2 \cdot H_{\text{Shannon}}$.

Substrate-mechanism reading: thermodynamic and information-theoretic entropy are the same operation on different bases. The substrate's natural information unit is the Reed-Solomon symbol on $\text{GF}(2^g) = \text{GF}(128)$ (Volume 14 Chapter 2); the substrate-natural entropy is

$$H_{\text{sub}}(X) = - \sum_n p_n \log_{128} p_n \quad (\text{substrate symbols})$$

with $\log_{128} = \log_2 / g$ — a factor of $g = 7$ relating substrate symbols to bits.

The Shannon-Boltzmann equivalence is not a coincidence; it is the substrate's information-content and the substrate's microstate-count being two readings of the same K-type configuration space.

3.4 The second law

The second law of thermodynamics: for any thermodynamic process,

$$\Delta S_{\text{total}} = \Delta S_{\text{system}} + \Delta S_{\text{environment}} \geq 0$$

with equality only for reversible processes.

The substrate-mechanism derivation: every Zone 3 commitment in the substrate cycle discards information (orthogonal-to-outcome amplitude leaks to environmental K-types). This is *irreducible* — Zone 3 is the substrate’s one non-unitary step (Volume 5 Chapter 7, K67 Born=Bergman). The discarded information becomes environmental entropy; the substrate-cycle-completed system has reduced “uncertainty” about its outcome.

Net result per tick: - System’s Gibbs entropy: ΔS_{sys} can be positive, negative, or zero depending on whether system K-type configurations spread (positive) or concentrate (negative) - Environment’s Gibbs entropy: ΔS_{env} discarded amplitude integrated over substrate-environment K-type couplings — always ≥ 0 by Zone 3 mechanism - Total: $\Delta S_{\text{total}} \geq 0$ always; equality only when Zone 3 commits with zero discard (degenerate case of pre-aligned amplitude).

This is the substrate-mechanism derivation of the second law.

3.5 SFP integration: entropy as multi-tick commitment-completion

Per Casey’s vision-derived Substrate Frame Principle (memory feedback_substrate_frame_principle.md, Casey 2026-05-24): the substrate’s Zone 3 commitment is not instantaneous — it spans many Koons ticks for complex systems, with decoherence time $\tau_D = N \cdot t_K$ where N is the substrate-derivable count of ticks to complete the commitment.

Entropy production scales with N : each tick of commitment-in-progress discards more environmental K-type amplitude, accumulating ΔS_{env} at rate proportional to substrate-environmental coupling. For macroscopic systems, $\tau_D \sim 10^{-30} \text{ s} = 10^{90}$ ticks of substrate commitment-completion $\rightarrow$ enormous total ΔS_{env} .

The second law is the substrate’s mandatory multi-tick information discard. The arrow of time is the substrate’s Zone 3 cycle direction.

3.6 Reversible vs irreversible processes

- Reversible: substrate cycles run with zero Zone 3 discard (or discard cancels via reverse-flow). $\Delta S_{\text{total}} = 0$. Idealized limit; no real process is exactly reversible.
- Irreversible: substrate cycles produce net Zone 3 discard. $\Delta S_{\text{total}} > 0$. All real processes.

Examples: - Heat conduction from hot to cold: substrate’s hot region commits its K-type amplitude to cold-region K-types, irreversible Zone 3 discard. - Friction:

kinetic K-types convert to thermal K-types via substrate Zone 3 commitment; the kinetic information is discarded into thermal environmental K-types. - Gas expansion into vacuum: substrate's gas-K-type amplitude spreads to new spatial K-types with no controlled emission; pure Zone 3 information-discard.

3.7 Entropy of mixing

When two ideal gases A and B (initially separated, N_A moles of A, N_B moles of B, both at temperature T , pressure P , volumes V_A , V_B) are mixed in total volume $V_A + V_B$:

$$\Delta S_{\text{mixing}} = -R[N_A \ln x_A + N_B \ln x_B]$$

where $x_A = N_A/(N_A + N_B)$, $x_B = N_B/(N_A + N_B)$ are mole fractions. Always positive (since $\ln x < 0$ for $x < 1$).

Substrate-mechanism: mixing combines K-types from two substrate sub-populations; the combined population has more accessible K-type configurations; entropy $= k_B \ln(\text{combined count})$ increases.

3.8 The Gibbs paradox and indistinguishability

The Gibbs paradox: if we apply the mixing formula to mixing *identical* gases (gas A with itself), we get $\Delta S_{\text{mixing}} > 0$ — but no real entropy change occurs. The resolution: identical particles are *truly indistinguishable* at the substrate level (Volume 5 Chapter 9 spin-statistics); the substrate K-type count doesn't increase upon "mixing" identical-K-type populations because they were already accessible.

Substrate reading: indistinguishability is the substrate's Pin(2) particle-exchange rule applied to K-type counting. The Gibbs paradox dissolves at the substrate level.

3.9 Third law (Nernst): $S \rightarrow 0$ as $T \rightarrow 0$

The third law: as $T \rightarrow 0$, the entropy of any system approaches a constant (often taken as zero for pure perfect crystals). This reflects the substrate having only one K-type accessible at $T = 0$ — the ground state.

For BST: $T = 0$ corresponds to the substrate's pre-Zone-1 state with no environmental coupling; only the ground-state K-type (Volume 5 Chapter 1 trivial K-type) is occupied; $W(E_0) = 1$; $S = k_B \ln 1 = 0$.

3.10 Worked example: entropy of an ideal gas

For monoatomic ideal gas of N particles in volume V at temperature T :

$$S(N, V, T) = Nk_B \left[\frac{5}{2} + \ln \left(\frac{V}{N} \left(\frac{2\pi m k_B T}{h^2} \right)^{3/2} \right) \right]$$

(Sackur-Tetrode equation, with quantum corrections via h). Substrate reading: the Sackur-Tetrode formula counts substrate K-types in phase space (volume $V \times$ momentum cube proportional to $T^{3/2}$) with the indistinguishability factor $N!$ accounted via the $\ln(V/N)$ form.

For $N = 1$ mole of argon at $T = 298$ K, $V = 24.5$ L: $-S \approx 154.8$ J/(K·mol) - Substrate K-type count $W \approx e^{S/k_B} \approx e^{1.87 \times 10^{25}}$ — astronomically huge

3.11 K-audit anchors

- Casey's Principle (memory): entropy = force = counting at depth 0
- SFP candidate (Casey 2026-05-24) (memory): multi-tick commitment-completion as entropy-generation mechanism
- K67 Born=Bergman (Volume 5 Chapter 7): Zone 3 commitment as substrate non-unitary step (foundation for second law)
- Volume 14 Chapter 2: Reed-Solomon on GF(128) (substrate symbol basis for Shannon entropy)
- Volume 14 Chapter 3: Shannon channel capacity

Level 3 — 5th-grader accessibility

Entropy is counting. If you have a deck of cards arranged perfectly (Ace through King in each suit), there's only one way that can look — low entropy. If you shuffle the deck, there are $52! \approx 8 \times 10^{67}$ ways the deck can look — high entropy. Entropy goes up because there are way more shuffled arrangements than ordered ones. That's the second law in one sentence: "the substrate counts, and more-numerous configurations are more numerous." Heat flows from hot to cold because there are more ways to spread the energy out than to keep it concentrated. Engines turn heat into work but always with leftover heat dumped to a cold reservoir, because the substrate has to discard information in its Zone 3 commitment step — no Zone 3 = no measurement = no irreversibility = no engines work. The information-theory version (Shannon) and the thermodynamic version (Boltzmann) are *the same operation* on the substrate's Reed-Solomon symbols.

What comes next

Chapter 4 develops free energies (Helmholtz $F = U - TS$, Gibbs $G = H - TS$) and Maxwell relations — Legendre transforms of internal energy adapted to different experimental boundary conditions.

Where to look this up

- Boltzmann entropy: Boltzmann 1872, 1877
- Gibbs entropy: Gibbs 1902, *Elementary Principles in Statistical Mechanics*
- Shannon entropy: Shannon 1948

- Second law: Clausius 1865; Carnot 1824
- Sackur-Tetrode: Sackur 1911; Tetrode 1912
- BST anchors: Casey's Principle, SFP candidate (Casey 2026-05-24), K67
Born=Bergman
- Volume 0 Chapter 3: 4-zone commitment cycle
- Volume 14 Chapter 3: Shannon channel capacity (info-theoretic reading)
